Consider a two-party communication problem, in which the participants

(a) Alice

and

(b) Bob

participate to compute a function:

$$f : \underbrace{\mathbb{B}^n}_{\text{Alice's input}} \times \underbrace{\mathbb{B}^n}_{\text{Bob's input}} \rightarrow \underbrace{\mathbb{B}}_{\text{global output}}$$

Example (Are the number of 1s in xy even (0), or odd (1)?)

$f : \mathbb{B}^n \times \mathbb{B}^n \rightarrow \mathbb{B}$ is precisely $(x, y) \mapsto \bigoplus xy$.

Example protocol Π :

$$P1 = \text{parity}(x).$$

$$P2 = \text{parity}(y) \oplus P1$$

Now both Alice and Bob know $f(x, y) = P2$. $C(f) \leq 2$ because $C(\Pi) = 2$ and Π implements f . But $C(f) \geq 2$ because f depends on x and y . Hence $C(f) = 2$.

Idea: an efficient protocol will efficiently **group together inputs that go to the same output**.

Definition (Fooling Set)

If $f : \mathbb{B}^n \times \mathbb{B}^n \rightarrow \mathbb{B}$ is a function, a *fooling set* for f is a set $S \subseteq \mathbb{B}^n \times \mathbb{B}^n$ such that for some choice $b \in \mathbb{B}$ $f(S) = \{b\}$ but, for all distinct $(x, y), (x', y') \in S$, $(\neg b) \in f(\{x, x'\} \times \{y, y'\})$.

Basically, a fooling set is a group of inputs that go to the same output, but which is *brittle* to argument-swapping. In some sense these *brittle* sets lower-bound the difficulty in grouping like inputs.

NTS: If f has a size- M fooling set then $C(f) \geq \log_2(M)$.

Proof.

For a contradiction suppose a protocol Π exists for f s.t. $C(\Pi) < \log_2(M)$. Then Π yields at most $2^{C(\Pi)} < 2^{\log_2(M)} = M$ distinct communication patterns. But there are $M * (M - 1)$ disjoint choices of $(x, y), (x', y') \in S$. Since $M * (M - 1) > M$ there must be some $(x, y), (x', y')$ on which Π yields the same communication pattern.

NTS: If f has a size- M fooling set then $C(f) \geq \log_2(M)$.

Proof.

For a contradiction suppose a protocol Π exists for f s.t. $C(\Pi) < \log_2(M)$. Then Π yields at most $2^{C(\Pi)} < 2^{\log_2(M)} = M$ distinct communication patterns. But there are $M * (M - 1)$ disjoint choices of $(x, y), (x', y') \in S$. Since $M * (M - 1) > M$ there must be some $(x, y), (x', y')$ on which Π yields the same communication pattern.

Then (x, y') must yield the same communication pattern as (x, y) as Bob cannot possibly tell the difference. The argument is symmetric for (x', y) and Alice. One of the two must yield a contradiction and we are done. \square

$$\text{NTS: } C(f) \leq 16(\log_2 \chi(f))^2. [1]$$

Proof.

Each stage proceeds as follows.

- 1 Alice looks for a rectangle $M_i = X_i \times Y_i$ s.t. $x \in X_i$ and $\deg_L(i) \leq 3\chi(f)/4$.
 - 1 If she finds some such rectangle then she sends i to Bob.
 - 1 Bob replies to indicate if $y \in M_i$.
 - 2 If so then the protocol ends because $f(x, y)$ is the color of M_i .
 - 3 Otherwise $X := X \cap X_i$, and each rectangle $M_\alpha = X_\alpha \cap Y_\alpha$ is replaced with $(X_i \cap X_\alpha) \times Y_\alpha$.
 - 2 Otherwise she replies that she found no such rectangle. In this case Bob does what Alice just attempted, symmetrically, with a small caveat ...

NTS: $C(f) \leq 16(\log_2 \chi(f))^2$. [1]

Proof.

- If neither Alice nor Bob could find any M_i with low-enough degree, then they both know that every node i in $G := G_L \cap G_R$ for which $(x, y) \in M_i$ has degree $\geq (3\chi(f)/4)^2 = 9\chi(f)/16 > \chi(f)/2$.
- Let i, j both have degree $\geq \chi(f)/2$ in G . Then some node z is adjacent to i and j in G , by the Pigeonhole Principle. Hence $M_i \cap M_z = \emptyset$ and $M_j \cap M_z = \emptyset$. But the rectangles are monochromatic, hence, M_i and M_j are the same color. So Alice needs to find an M_i containing x and some $y \in Y$ whose degree in G is at least $\chi(f)/2$; and Bob's procedure is symmetric.

NTS: $C(f) \leq 16(\log_2 \chi(f))^2 \cdot [1]$

Proof.

- In the worst case for each stage, the first participant sends “nothing found” (1 bit), the second participant sends some i ($\leq \log_2(\chi(f))$ bits), and the first participant replies with some j ($\leq \log_2(\chi(f))$ bits). So in the worst case each round requires $\leq 2 + 2\log_2(\chi(f))$ bits.
- The protocol ends after at most n rounds where $(3\chi(f)/4)^n \approx 1$, i.e., after $\log_{(4/3)}(\chi(f))$ rounds.
- So total communication complexity is $\leq \log_{(4/3)}(\chi(f)) * (1 + 2\log_2(\chi(f)))$.

When we partition $M(f)$ into some number of rectangles, the sizes of the rectangles must add up to the size of $M(f)$.

Hence, if $\chi(f) \leq K$ for some integer K , then $M(f)$ must have a m.c. rectangle containing at least $2^n * 2^n / K$ entries.

Proof.

Suppose $\chi(f) \leq K$ for some integer K . If $\chi(f) = K$ then \exists a partitioning of $M(f)$ into K m.c. rects, in which case at least 1 must have size $\geq |M(f)|/K$, i.e., $2^n * 2^n / K$. On the other hand if $\chi(f) < K$ then $\chi(f) = K'$ for some $K' < K$ and then $M(f)$ can be partitioned into K' monochromatic rectangles, at least 1 of which has size $\geq |M(f)|/K'$, which is strictly larger than $|M(f)|/K$. Either way the conjecture holds. \square

$$\frac{1}{2^n * 2^n} \left| \sum_{a \in A, b \in B} (-1)^{M_{a,b}} \right| \geq 1/K$$

Mathematicians like to name things.

Definition (Discrepancy)

The *discrepancy* of a rectangle $A \times B$ of $M(f)$ is exactly the following.

$$\text{Disc}(A \times B) = \frac{1}{2^n * 2^n} \left| \sum_{a \in A, b \in B} (-1)^{M_{a,b}} \right|$$

The *discrepancy* of $M(f)$ is the max disc among its rectangles.

Although somewhat scary-looking, this definition pays dividends immediately.

Lemma (k -Party Discrepancy Bound)

If $f : (\mathbb{B}^n)^k \rightarrow \mathbb{B}$ is a function, then $\text{Disc}(f) \leq (\mathcal{E}(f))^{1/2^k}$.

Proof sketch:

Proof.

Given any cylinder intersection and (n, k) -cube, what is the expectation / the image of the cube? What if we only consider points in the cylinder intersection? Derive a lower bound on $\mathcal{E}(f)$ like

$$\mathcal{E}(f) \geq E_{x_1, \dots, x_k} [f(x_1, \dots, x_k) (1 \text{ if } (x_1, \dots, x_k) \in C \text{ else } 0)]^{2^k}$$

given a cylinder intersection C . Argue from the def. of the k -party discrepancy that this gives a natural lower-bound $\mathcal{E}(f) \geq \text{Disc}(f)^{2^k}$. But this implies $\text{Disc}(f) \leq (\mathcal{E}(f))^{1/2^k}$, and we're done. □
